Email: jimrock69@comcast.net

The distribution of prime constellations, from twin primes to dense k-tuples, is often studied asymptotically. However, the transition of these patterns from one prime scale to the next follows a rigid mechanical structure. This paper presents a recursive inequality that governs the propagation of admissible prime constellations between consecutive prime intervals. We define a “Prime Region” as the interval bounded by a prime P_n and its square P_n^2 . We demonstrate that the count of any symmetric k-tuple in a new region is strictly bounded below by the count in the previous region, modulated by a geometric growth factor. By analyzing the “Territory Expansion” of the number line against the “Density Decay” of the prime sieve, we identify a massive “Safety Margin” inherent in the geometry of integers. We generalize this mechanism to symmetric k-tuples, introducing the concept of “Sieve Resilience” to construct optimal search centers for large constellations. This framework reveals that the quadratic expansion of the search space (P^2) consistently overpowers the linear growth of the sieve density ($k \cdot P$), providing a constructive mechanism for the infinite propagation of not just twin primes, but all admissible symmetric constellations.

1 Introduction and Definitions

To formalize the transition between prime scales, we define the following terms:

- **Prime Region (R_n):** The interval of integers bounded by a prime P_n and its square P_n^2 . This region represents the “Horizon of Certainty” for the sieve; for any $x < P_n^2$, primality is determined entirely by factors $q \leq P_n$.
- **Admissible k-Tuple:** A repeating constellation of k primes formed by a base prime p and a fixed set of even integer offsets $\mathcal{D} = \{d_1, d_2, \dots, d_{k-1}\}$.

- *Condition*: The tuple is “admissible” if the offsets do not cover all residue classes modulo any prime q .
- *Example*: $\{p, p+2, p+4\}$ is not admissible (covers all mod 3). $\{p, p+2, p+6\}$ is admissible.
- **Symmetric Prime k-Tuple**: A specific subclass of admissible constellations where the primes are pairwise symmetric around a central value C .
 - *Center*: $C = (q_1 + q_k)/2$.
 - *Structure*: For every prime $C - d$ in the tuple, there is a corresponding prime $C + d$.
 - *Minimality*: We focus on tuples with minimal diameter ($H = q_k - q_1$) to analyze the tightest possible sieve constraints.
- **Sieve Resilience**: A property of specific search centers (e.g., $C = 105 + 210n$) that are pre-aligned to be coprime to small primes (2, 3, 5, 7). This effectively reduces the sieve’s “Density Decay” to zero for the initial, most destructive steps.
- **Territory Expansion (Supply)**: The quadratic growth of the Prime Region ($P_{n-1}^2 \rightarrow P_n^2$), which generates a massive supply of new integer candidates.
- **Density Decay (Demand)**: The linear filtering cost of the sieve, where each new prime P_n eliminates a fraction of the candidates (approximately k/P_n).

The distribution of twin primes—and more generally, prime k-tuples—is traditionally approached through asymptotic probabilistic models. However, to derive a governing inequality for these constellations, we must move beyond asymptotic averages and examine the mechanical transition between prime intervals.

We model this transition as a physical process involving two competing rates:

1. **Expansion (The Supply)**: We calculate the multiplicative increase in the number line interval (the “Territory”) as we move from P_{n-1} to P_n .
2. **Decay (The Demand)**: We calculate the multiplicative decrease in constellation density caused by the sieving effect of the new prime P_n .
3. **Net Interaction**: We multiply these two rates to determine the Expected Net Growth.

This paper posits a **Constructive Hypothesis**: The geometry of the number line ensures that the “Supply” of new territory consistently outpaces the “Demand” of the density decay. We define a massive “Safety Margin” inherent in this geometry ($1 + 2c/P$ vs $1 + c/P$), ensuring that the accumulation of new candidates provides a constructive mechanism for the infinite propagation of twin primes and, by extension, all admissible symmetric k-tuples.

2 Theoretical Framework: The Constructive Hypothesis

While the distribution of twin primes and k-tuples is traditionally analyzed through asymptotic averages (e.g., the Hardy-Littlewood conjectures [2], such probabilistic models describe the *expected* density over large scales but do not strictly preclude local voids. To establish a rigorous lower bound, we must shift from an asymptotic

perspective to a *constructive* one, modeling the transition between prime intervals as a deterministic mechanical process.

2.1 The Supply-Demand Dynamics

We propose the “Constructive Hypothesis,” which treats the number line not as a static set of integers, but as a dynamic terrain governed by two competing forces:

1. **Geometric Supply (The Expansion):** As the analysis moves from P_{n-1} to P_n , the interval under consideration expands from P_{n-1}^2 to P_n^2 . This expansion is quadratic.
2. **Arithmetic Demand (The Decay):** Simultaneously, the introduction of P_n as a new sieve filter removes candidates from this expanded territory. This removal process is linear (removing 2 residue classes for twin primes, or k for k -tuples).

The core of our framework is the interaction between these two rates. Because the “Territory Supply” grows quadratically while the “Sieve Demand” grows only linearly, there exists a structural surplus of candidates. The Constructive Hypothesis asserts that this surplus is not accidental but is a fundamental geometric property that ensures the population of constellations can never reach zero.

2.2 The Logic of the Lower Bound

The derivation in the subsequent sections relies on identifying a specific “Safety Margin.” Rather than attempting to predict the *exact* count of twin primes (which fluctuates due to local randomness), we construct a recursive inequality that demands only a fraction of the theoretical growth.

By proving that the physical expansion of the number line $(1 + 2c/P)$ consistently exceeds the requirements of our recursive formula $(1 + c/P)$, we establish an unbreakable “floor” for the population count. This approach effectively dampens the variance inherent in prime distributions, allowing us to define a minimum propagation rate that holds true regardless of local irregularities in the sieve.

3 Derivation of Component Rates

3.1 Step 1: The Expansion Rate

First, we quantify the growth of the interval. The length of the previous interval is $L_{n-1} \approx P_{n-1}^2$. The length of the current interval is $L_n \approx P_n^2$. Substituting $P_n = P_{n-1} + c$, the multiplicative expansion rate is:

$$R_E = \frac{P_n^2}{P_{n-1}^2} = \left(\frac{P_{n-1} + c}{P_{n-1}} \right)^2 = \left(1 + \frac{c}{P_{n-1}} \right)^2 \quad (1)$$

Expanding the square yields the precise geometric growth factor:

$$R_E = 1 + \frac{2c}{P_{n-1}} + \frac{c^2}{P_{n-1}^2} \quad (2)$$

This confirms that the "Supply" of new numbers grows linearly with the gap $(2c/P)$ and includes a quadratic bonus (c^2/P^2) .

3.2 Step 2: The Decay Rate

Next, we quantify the "Demand" of the sieve. The new prime P_n removes candidates where $x \equiv 0 \pmod{P_n}$ or $x+2 \equiv 0 \pmod{P_n}$. The probability of a candidate surviving this new filter is:

$$R_D = \frac{P_n - 2}{P_n} = 1 - \frac{2}{P_n} \quad (3)$$

To maintain a strict lower bound, we can approximate the denominator with P_{n-1} (since $P_n > P_{n-1}$, subtracting $2/P_{n-1}$ is a slightly harsher penalty than reality, keeping us conservative).

$$R_D \approx 1 - \frac{2}{P_{n-1}} \quad (4)$$

4 Synthesis of the Transfer Function

The expected number of twin primes in the new interval ($TPA_{expected}$) is the product of the old count, the expansion rate, and the decay rate.

$$R_{net} = R_E \times R_D \quad (5)$$

Substituting the terms derived above:

$$R_{net} \approx \left(1 + \frac{2c}{P_{n-1}} + \frac{c^2}{P_{n-1}^2}\right) \cdot \left(1 - \frac{2}{P_{n-1}}\right) \quad (6)$$

We expand this product term by term to find the *Theoretical Net Growth*:

$$R_{net} \approx 1 \cdot \left(1 - \frac{2}{P}\right) + \frac{2c}{P} \cdot \left(1 - \frac{2}{P}\right) + \frac{c^2}{P^2} \cdot \left(1 - \frac{2}{P}\right) \quad (7)$$

$$\approx 1 - \frac{2}{P} + \frac{2c}{P} - \frac{4c}{P^2} + \frac{c^2}{P^2} - \dots \quad (8)$$

Grouping the dominant linear terms $(\frac{1}{P})$ and quadratic terms $(\frac{1}{P^2})$:

$$R_{net} \approx 1 + \frac{2c-2}{P_{n-1}} + \frac{c^2-4c}{P_{n-1}^2} \quad (9)$$

Result: The *Theoretical* growth of the twin prime population is driven by the linear term $\frac{2c-2}{P_{n-1}}$.

5 Construction of the Lower Bound Inequality

We have established that the *Theoretical Growth* is approximately $1 + \frac{2c-2}{P_{n-1}}$. However, relying on an average expectation is not sufficient for a proof.

To create a robust inequality that accounts for local variance, we introduce a **Safety Factor of 2**. We construct the recursive formula (Equation 10) to demand only **half** of the theoretical linear growth.

5.1 Comparing Theoretical vs. Required Growth

- **Theoretical Expectation:** $1 + \frac{2c-2}{P_{n-1}}$
- **Formula Requirement (Equation 10):** $1 + \frac{2c-2}{2P_{n-1}}$

Notice the denominator in the formula is $2P_{n-1}$ rather than P_{n-1} . This mathematically encodes the "Safety Margin."

Justification: Since the physical geometry of the number line provides roughly twice as much net expansion ($\frac{2c-2}{P}$) as the inequality requires ($\frac{2c-2}{2P}$), the actual count TPA_n will strictly exceed the value predicted by the formula for all sufficiently large P_n .

This derivation proves that Equation (10) is not arbitrary; it is a dampened version of the geometric expansion rate, designed to serve as an unbreakable lower floor.

6 The Recursive Growth Formula

Having established the theoretical framework and the necessary safety margin, we now formalize the governing inequality. This formula does not merely describe an observation; it represents the mechanical lower bound derived from the competition between Territory Expansion and Density Decay.

By applying the Safety Factor of 2 to the theoretical growth rate, we define a "Transfer Function" that relates the twin prime count in the current interval (TPA_n) to the count in the previous interval (TPA_{n-1}). As validated by the empirical data in Table 1, the inequality is:

$$TPA_n > (TPA_{n-1}) \cdot \left(1 + \frac{2c-2}{2P_{n-1}} + \frac{c^2-2c}{2P_{n-1}^2} \right) \quad (10)$$

6.1 Formula Mechanics

This formula balances two competing forces:

1. **Expansion Terms (c, c^2):** The terms involving c and c^2 quantify the physical expansion of the number line (the new territory).
2. **Normalization (P_{n-1}):** The denominator normalizes this growth against the sieving effect of the new prime.

The existence of the quadratic term (c^2) in the numerator is crucial; it ensures that the "supply" of new numbers grows faster than the "demand" of the sieve.

7 Generalization for Larger Gaps

For $c > 2$ the safety margin established above assumed the worst-case scenario ($c = 2$). For larger gaps, the margin expands significantly.

Comparing the growth terms:

- **Formula Demand:** The dominant linear term is $\frac{c}{P}$.
- **Territory Supply:** The physical expansion is roughly $\frac{2c}{P}$.

As c increases, the "Supply" of new integers outpaces the "Demand" of the formula by a factor of roughly 2 : 1. Furthermore, the quadratic term (c^2) in the physical expansion ensures that the territory term always dominates the linear density adjustments.

8 Empirical Verification

Table 1 compares the actual twin prime counts (TPA_n) against the values predicted by the recursive inequality. The ratio F/G (Calculated/Actual) consistently approaches 1 from below, confirming the inequality is a tight lower bound.

P_n	TPA_{n-1}	Calc. Lower Bound	Actual TPA_n	Ratio
1021	8450	8524.8	8586	0.992
3463	68872	68931.7	69019	0.998
26863	2555371	2556798.3	2558027	0.999
31321	3365489	3366026.3	3366653	0.999

9 Algorithmic Optimization for Symmetric Prime k-tuples

The mechanism of "Quadratic Overpowering" demonstrates that within local search intervals $[P_n, P_n^2]$, the spatial expansion of the number line structurally buffers against the linear density degradation of the prime sieve. While establishing absolute global bounds for infinity remains a classical open problem, this framework can be generalized to define a highly deterministic optimization model for locating dense, symmetric k -tuples. We show that by mechanically aligning search centers with primordial structures, we can reduce the initial sieve degradation to zero and structurally maximize local density parameters.

9.1 Supply vs. Demand Dynamics in Algorithmic Search

When executing a search for a constellation of k primes defined by an array of symmetric integer offsets $\mathcal{D} = \{\pm d_1, \pm d_2, \dots, \pm d_{k/2}\}$, the computational efficiency is governed by the net interaction of two distinct forces:

1. **Geometric Supply (Constant):** The "Territory Expansion" is an intrinsic property of the interval $[P_n, P_n^2]$ itself. It generates candidate space at a rate of approximately $1 + \frac{2c}{P_n}$, independent of the configuration under evaluation.
2. **Arithmetic Demand (Variable):** The "Density Decay" represents the filtering cost of the sieve. For a random or unaligned search center, the introduction of a prime filter P_n removes up to k distinct residue classes, decreasing candidate density by a factor of approximately k/P_n .

In an unoptimized search window, the probability of a random integer center supporting a highly dense configuration (such as $k = 8$ or $k = 10$) is vanishingly small due to this compounding linear decay.

9.2 Constructive Center Selection via Sieve Resilience

To maximize candidate survival rates, we define a search center C as *Sieve Resilient* up to a prime boundary p_m if the offset array $\mathcal{D}$ is completely disjoint from the residue class of C modulo p for all $p \leq p_m$:

$$C + d_i \not\equiv 0 \pmod{p} \quad \forall d_i \in \mathcal{D}, \quad \forall p \leq p_m \quad (11)$$

By constructing search coordinates based on primorial steps $M_m = \prod_{p \leq p_m} p$, we pre-align our search environments to neutralize the filtering effect of the smallest, most computationally destructive primes.

9.3 Algorithmic Application: The Symmetric Decuplet (D₁₀)

Consider a symmetric 10-tuple ($k = 10$) with a spatial diameter of 44, defined by the offset array $\mathcal{D} = \{\pm 2, \pm 4, \pm 8, \pm 16, \pm 22\}$. To maximize local candidate survival, we restrict the search space exclusively to coordinates generated by the primorial arithmetic progression:

$$C(n) = 105 + 210n \quad (12)$$

where $M_4 = 2 \cdot 3 \cdot 5 \cdot 7 = 210$, and 105 is the symmetric balancing point. This algorithmic alignment guarantees absolute resilience against the first four prime sieves:

- **Modulo 2:** $C(n)$ is identically odd. Because all elements in $\mathcal{D}$ are even, $C(n) \pm d_i$ is guaranteed to be odd, yielding a 0% filtration rate for $p = 2$.
- **Modulo 3:** $C(n) \equiv 0 \pmod{3}$. Because no offset in $\mathcal{D}$ is divisible by 3, $C(n) \pm d_i \not\equiv 0 \pmod{3}$, yielding a 0% filtration rate for $p = 3$.
- **Modulo 5:** $C(n) \equiv 0 \pmod{5}$. Because no offset in $\mathcal{D}$ is divisible by 5, $C(n) \pm d_i \not\equiv 0 \pmod{5}$, yielding a 0% filtration rate for $p = 5$.
- **Modulo 7:** $C(n) \equiv 0 \pmod{7}$. Because no offset in $\mathcal{D}$ is divisible by 7, $C(n) \pm d_i \not\equiv 0 \pmod{7}$, yielding a 0% filtration rate for $p = 7$.

By pre-satisfying these modular constraints, the effective sieve demand is driven to zero during the opening phases of the search space, leaving the localized candidate density dependent solely on prime factors $P > 7$.

9.4 Quantification of Localized Sieve Efficiency

To evaluate the mathematical impact of Sieve Resilience, we distinguish between the raw constellation size k and the effective sieve demand $k_{eff}(P_n)$. We define k_{eff} as a piecewise function of the current sieve index:

$$k_{eff}(P_n) = \begin{cases} 0 & \text{if } P_n \leq 7 \\ \nu_{\mathcal{D}}(P_n) \leq k & \text{if } P_n > 7 \end{cases} \quad (13)$$

where $\nu_{\mathcal{D}}(P_n)$ represents the exact number of distinct residue classes occupied by $\mathcal{D}$ modulo P_n .

Substituting this optimized parameter into our local transfer function yields a localized inequality tracking candidate density inside the resilient windows:

$$TPA_{n(k)} > (TPA_{n-1(k)}) \cdot \left(1 + \frac{2c - k_{eff}(P_{n-1})}{2P_{n-1}} + \frac{c^2 - k_{eff}(P_{n-1})c}{2P_{n-1}^2} \right) \quad (14)$$

Because $k_{eff} = 0$ for all steps up to $p = 7$, the negative filtration terms vanish entirely during the initial expansion. This generates a massive local candidate surplus that accelerates computational search times, a phenomenon empirically verified by the deep-search discoveries recorded in Section 11. Supplement.

9.5 Heuristic Mapping to the Hardy-Littlewood Singular Series

The efficiency achieved by our localized Sieve Resilience algorithm can be rigorously mapped onto the classical asymptotic limits of the integer field. For a constellation with offsets $\mathcal{D}$, the expected density of occurrences over large scales is modulated by the unproven **Hardy-Littlewood Singular Series** $\mathfrak{S}(\mathcal{D})$ [2]:

$$\mathfrak{S}(\mathcal{D}) = \prod_{p \geq 2} \left(1 - \frac{\nu_{\mathcal{D}}(p)}{p} \right) \left(1 - \frac{1}{p} \right)^{-k} \quad (15)$$

Our constructive progression $C(n) = 105 + 210n$ acts directly upon the leading coefficients of this infinite product. By forcing $\nu_{\mathcal{D}}(p) = 0$ for $p \leq 7$, we algorithmically amplify the initial multiplier of the series:

$$\mathfrak{S}_{Resilient}(\mathcal{D}) = \left[\prod_{p \leq 7} \left(1 - \frac{1}{p} \right)^{-k} \right] \times \prod_{p > 7} \left(1 - \frac{\nu_{\mathcal{D}}(p)}{p} \right) \left(1 - \frac{1}{p} \right)^{-k} \quad (16)$$

Because the finite product bounded by $p \leq 7$ yields a strict density maximization multiplier, it mathematically explains the localized survival of these dense configurations. As long as $\mathcal{D}$ remains admissible, $\mathfrak{S}_{Resilient}(\mathcal{D}) > 0$ holds true. When synthesized with our local transfer inequality, this optimization shows that while a global proof of infinity remains conditional on the broader Hardy-Littlewood framework, our primordial selection mechanism provides a highly predictable, mathematically optimized substrate for targeted constellation hunting.

9.6 Analytical Boundaries and Scaling Constraints

While this framework provides a deterministic acceleration model for localized searches up to $k = 10$, we note that the optimization model encounters strict geometric boundary constraints as the constellation size scales.

As the size of the target constellation expands toward an arbitrary $2n$ -tuple, the physical diameter of the required offset array $\mathcal{D}$ inevitably widens. Once the spatial

span of these offsets exceeds the static primorial modulus $M_4 = 210$, the elements of the constellation necessarily begin to intersect with the next un-neutralized prime filters in the sieve sequence ($p = 11, 13, 17, \dots$).

Consequently, the effective sieve demand k_{eff} leaks back into the linear numerator of the local transfer function, reintroducing localized variance. To maintain a constant efficiency rating for larger arbitrary constellations, the primorial base must scale dynamically as a function of the constellation diameter:

$$M_k = \prod_{p \leq p_k} p \quad (17)$$

This architectural scaling property represents the primary roadmap for future computational expansion within this framework.

10 Conclusion

The distribution of dense prime constellations has historically been modeled via purely stochastic averages. This paper has demonstrated that the localized tracking of these patterns can be approached as a deterministic mechanical process governed by the geometry of prime regions $[P_n, P_n^2]$.

By formalizing the competitive interaction between quadratic Territory Expansion and linear Density Decay, we isolated a robust, repeatable lower bound governing candidate propagation in localized search windows. Furthermore, by introducing the concept of primorial-aligned Sieve Resilience, we demonstrated a highly efficient method for neutralizing the filtering costs of the most destructive early prime sieves.

The empirical computational results detailed in the Supplement—culminating in the discovery of isolated symmetric decuplets at magnitude 3.4×10^{10} and 1.1×10^{11} —provide strong validation for this optimization framework. We conclude that while an unconditioned global proof for the infinite propagation of k -tuples remains bound to classical open conjectures, the constructive mechanics of primorial coordinate alignment provide a powerful, mathematically rigorous toolkit for optimizing the discovery of complex prime structures within the integer field.

A Experimental Verification of Symmetric Constellations

To validate the Constructive Hypothesis, we employed a computational search to identify specific, rigid symmetric constellations. We present two cases: a symmetric octuplet (8-tuple) used as a pedagogical example, and a symmetric decuplet (10-tuple) found via deep search to demonstrate the method’s robustness.

A.1 Case 1: The Symmetric Octuplet (D_8)

We first defined a symmetric pattern with a diameter of 32, centered at C , using power-of-2 offsets:

$$\delta_8 = \{\pm 2, \pm 4, \pm 8, \pm 16\} \quad (18)$$

A.2 Search Protocol

We utilized the “Sieve Resilience” generator derived in Section 10:

$$C(n) = 105 + 210n \quad (19)$$

This generator guarantees that all candidates are coprime to 2, 3, 5, and 7.

A.3 Results

The search identified the first valid symmetric octuplet almost immediately ($n = 931$), demonstrating the high efficiency of the selection method for smaller tuples.

Center: $C = 195,615$

Primes: $\{195599, 195607, 195611, 195613, 195617, 195619, 195623, 195631\}$

The search identified the second valid symmetric octuplet almost quickly ($n = 1166$),

Center: $C = 244, 965$

Primes: $\{244949, 244957, 244961, 244963, 244967, 244969, 244973, 244981\}$

A.4 Case 2: The Symmetric Decuplet (D_{10})

We extended the search to a symmetric 10-tuple with a diameter of 44, adding the offset ± 22 :

$$\delta_{10} = \{\pm 2, \pm 4, \pm 8, \pm 16, \pm 22\} \quad (20)$$

This pattern is significantly harder to locate due to the modular constraints at $P = 11$ (where only centers $C \equiv 1, 10 \pmod{11}$ survive).

A.5 Results

The computational search (using the script in 11.1.6) successfully identified the first occurrence of this constellation at iteration $n = 165, 871, 800$.

Iteration: $n = 165, 871, 800$

$$C(n) = 105 + 210n \quad (21)$$

Center: $C = 34, 833, 078, 105$

$$C(n) = 105 + 210n \quad (22)$$

The Primes:

34833078083, 34833078089, 34833078097, 34833078101, 34833078103,
34833078107, 34833078109, 34833078113, 34833078121, 34833078127

The computational search (using the script in 11.1.6) successfully identified the second occurrence of this constellation at iteration $n = 543, 417, 978$.

Iteration: $n = 543, 417, 978$ Gap from previous Decuplet: 377546178 steps

$$C(n) = 105 + 210n \quad (23)$$

Center: $C = 114, 117, 775, 485$

The Primes:

114117775463, 114117775469, 114117775477, 114117775481, 114117775483,
114117775487, 114117775489, 114117775493, 114117775501, 114117775507

This result confirms that even for highly constrained patterns requiring deep searches (magnitude 11.4×10^{10}), the “Supply” of new territory eventually yields the necessary configuration, as predicted by the Constructive Hypothesis.

A.6 Source Code

The following Python script was used to locate the symmetric decuplet. It utilizes dynamic primality testing to search the number line without a pre-computed database.

```

1 from sympy import isprime
2 import time
3
4 def find_symmetric_decuplet():
5     # Target offsets for Diameter 44
6     offsets = [2, 4, 8, 16, 22]
7
8     # Start search
9     n = 1
10    found = False
11
12    print("Searching for symmetric 10-tuple...")
13
14    while not found:
15        # Construct the center with Sieve Resilience
16        center = 105 + (210 * n)
17
18        # Optimization: Mod 11 check
19        # Center must be 1 or 10 mod 11 to survive
20        rem = center % 11
21        if rem != 1 and rem != 10:
22            n += 1
23            continue
24
25        candidates = []
26        possible = True
27
28        for osc in offsets:
29            lower = center - osc
30            upper = center + osc
31            # Fail fast if composite
32            if not isprime(lower) or not isprime(upper):
33                possible = False
34                break
35            candidates.extend([lower, upper])
36
37        if possible:
38            found = True
39            candidates.sort()
40            print(f"--- FOUND at n={n} ---")
41            print(f"Center: {center}")
42            print(f"Primes: {candidates}")
43        else:
44            n += 1
45
